Eitt af skilyrðum Umhverfisráðherra fyrir leyfum til byggingar Kárahnjúkavirkjunar var að vakta dæmigerð botndýrasamfélög í Héraðsflóa. Árið 2006 (LV-2007/074) var þetta skoðað og í ljós kom að ekki var mikill munur á botndýrasamfélögum í Héraðsflói og tveimur viðmiðunar stöðum (Vopnafjörður og Borgarfjörður eystri) en greinilegt samband var á milli botngerðar og botndýrasamfélaga. Þessi rannsókn er endurtekning á þeirri athugun sem gerð var þá og er gerð til að meta hvort breytingar hafi orðið með tilkomu virkjunar. Niðurstöður eru á svipuðum nótum 2006, þó komu fram smávægilegar breytingar milli ára á stöð 1 sem liggur næst ósum í Héraðsflói hvað snertir botngerð, færri tegundir botndýra og breytingar á tegundasamsetningu. Þessar breytingar gætu tengst breytingum á framburði sem berst í Héraðsflói en gætu einnig verið árstíðabundinn breytileiki.

Summary and conclusions

The survey conducted in 2006 did not show large variation in faunal communities between Héraðsflói and the other two reference locations but showed rather similar communities based on sediment type. Two separate groupings were observed, where faunal communities in sandy sediments at the stations were considered as one group and communities in mixed and clayish sediments, were the other group. The results from the survey conducted in 2019 showed the same trend, where the faunal communities were grouped by sediment type, and not a distinct separation of Héraðsflói and the reference sites. However, it was observed that station 1 closest to the river input in Héraðsflói showed some changes in sediment composition, reduction in abundance and number of taxa and changes in taxa composition between 2006 and 2019 that could be related to river sediment discharges, but also annual changes. The overall taxonomical composition at the different study sites from 2019 is comparable to the case study in 2006 and no major changes related to the changed river outflow were apparent, but it is important to emphasise that any fluctuations in the years between the two surveys, were not covered.

Ágrip

Í fyrrri rannsókn sem gerð var árið 2006 kom ekki fram mikill munur á botndýrasamfélögum í Héraðsflóa og tveimur viðmiðunar stöðum (Vopnafjörður og Borgarfjörður eystri) en greinilegt samband var á milli botngerðar og botndýrasamfélaga. Tvær megin gerðir botndýrasamfélaga voru á öllu rannsóknarsvæðinu, samfélög botndýra á stöðvum með sandbotni var einn hópur og samfélög botndýra á stöðvum þar sem botngerð var blanda af sand- og leirbotni var annar hópur. Niðurstöður rannsóknar sem gerð var 2019 voru á svipuðum nótum þar sem skilgreina má botndýrasamfélög út frá botngerð og ekki kom fram afgerandi munur á milli botndýrasamfélaga í Héraðsflóa og viðmiðunarstaða (Vopnafjörður og Borgarfjörður eystri). Hins vegar komu fram smávægilegar breytingar milli ára á stöð 1 sem liggur næst ósum í Héraðsflóa hvað snertir botngerð, færri tegundir botndýra og breytingar á tegundasamsetningu. Pessar breytingar gætu tengst breytingum á framburði sem berst í Héraðsflóa en gætu einnig verið árstíðabundinn breytileiki. Heilt yfir er tegundasamsetning þeirra þriggja fjarða sem rannsakaðir voru sambærileg þegar bornar eru saman niðurstöður á milli áranna 2006 og 2019 og ekki komu í ljós neinar breytingar sem tengja má með beinum hætti við hugsanlegar breytingar í árframburði til Héraðsflóa. Mikilvægt er þó að hafa í huga að þessi rannsókn varpar ekki ljósi á breytingar eða sveiflur sem gætu hafa átt sér stað á árunum á milli þessar tveggja rannsókna.

1 Preface

Landsvirkjun, the National Power Company of Iceland, is operating several hydroelectric, geothermic and wind power plants, including the Kárahnjúkar hydropower plant in North East Iceland. Kárahnjúkar was started in 2007 and this has led to changes in the supplies of freshwater and sediment to the inlet Héraðsflóa.

Landsvirkjun has engaged Akvaplan-niva to carry out an environmental monitoring survey of the coast of Héraðsflóa, Borgarfirði eystri and Vopnafirði. The study is a follow up of the baseline study in 2006 (Ólafsdóttir *et al.*, 2007) performed prior to start-up of the Kárahnjúkar hydropower plant. Samples were collected during 26. June – 9. July 2019, and the results are compared to the 2006 results, to describe any changes in the bottom fauna and sediment conditions, ascribed to the operations at Kárahnúkavirkun.

The following personnel at Akvaplan-niva have contributed to the project:

Lars-Henrik Larsen	Project leader, field work, report writing.
Snorri Gunnarsson	Field work, report writing, coordination with client.
Rosalyn Fredriksen	Report writing, data analyses.
Roger Velvin	Identifying benthos (Varia).
Hans-Petter Mannvik	Identifying benthos (echinoderms and caudofoveates). QA report.
Rune Palerud	Identifying benthos (crustaceans), statistics.
Jesper Hansen	Identifying benthos (polychaeta and molluscs).
Charlotte P Ugelstad	Identifying benthos (polychaeta).
Thomas Heggem	Oceanographic data (CTDO-profiles).
Kristine H Sperre	Coordination of sorting of benthic samples.
Ingar H. Wasbotten	Coordination of geo-chemical sediment analyses.

Tromsø, December 2020

Lars-Henrik Larsen
Project leader

The project is carried out by Akvaplan-niva AS according to accredited procedures.

 NORSK AKKREDITERING TEST 079	Akvaplan-niva Ltd is accredited by Norwegian Accreditation, and according to NS-EN ISO/IEC 17025 for: Collection of sediment and fauna samples, sediment analyses of TOC (Total Organic Carbon), TOM (Total Organic Matter), TN (Total Nitrogen), grain size distribution and macrofauna identification, data interpretation and scientific evaluations. Accreditation number is TEST 079.
---	--

1 Introduction

1.1 Background information

The Kárahnjúkar dam located in east Iceland was installed in 2007, and is the tallest concrete-faced rockfill dam in Europe, with a maximum height of 198 m. The dam was constructed as a reservoir to a hydropower plant with a capacity of 690 MW and a volume of 8.5 million m³ (Landsvirkjun, 2020). Kárahnjúkar dam is connected to the large river Jökulsá á Fljótsdal and is a major source for freshwater- and riverine particulate supplies to the bay Héraðsflóa.

Installing a dam in the river system has changed the riverine intensity of freshwater, sedimentation and particles that reaches the sea, which again may affect the distribution and abundance of benthic marine fauna. Before the start-up of the power plant, a baseline survey of Héraðsflói was performed in May – June in 2006, including the neighbouring inlets Borgarfjörður and Vopnafjörður as reference sites. The present study collected samples in 2019 at the same stations as in 2006, and the surveys jointly enables comparison of the marine seafloor environment before- and after installation and operation of the hydroelectric power plant.

1.2 Study sites

1.2.1 Héraðsflói

Héraðsflói is a short (approx. 10 km) but broad (25 km) bay (Figure 1). The depth of the bay increases gradually towards the open sea and reaches 150 m at the outermost parts. There are no local sills. Héraðsflói gets direct freshwater input from two major rivers called Jökulsá í Fljótsdal and Jökulsa á Dal. Continuous sedimentation from the rivers shapes a delta at the inlet, which also slowly reduces the water depth of the bay. Before the installation of the hydroelectric power plant, the two rivers contributed around 8,5 million tonnes of sediment load to the bay per year (Hartman *et al.* 2017).

1.2.2 Reference sites Borgarfjörður eystri and Vopnafjörður

Borgarfjörður Eystri and Vopnafjörður are reference sites to Héraðsflói. Both reference sites are assumed not to be influenced by the large river effluents reaching Héraðsflói. Borgarfjörður eystri is the southernmost sampling area in this survey, 3 km in width and 5 km long. Depth in Borgarfjörður eystri is only about 50 m at the mouth of the fjord and depths of 100 and 150 m are subsequently about 5 and 13 km further out from the fjord's mouth. Vopnafjörður is about 17 km in width and 25 km long. Maximum depth is in the middle of the fjord (around 140 m) and up to 150 at the mouth of the fjord (Figure 1).

2 Materials and methods

2.1 Sampling method

The 2019 sampling stations were located along six transects (two in each fjord area), at 50-, 100- and 150 m water depth. These were the same stations that were used in 2006 (Ólafsdóttir *et al.* 2007). Each transect consisted of three stations, and at each station three replicates of benthic bottom fauna were collected using a 0.1 m² van Veen grab, and one replicate at each station was taken for sediment analyses. In total eighteen stations were covered in Héraðsflói, Borgarfjörður and Vopnafjörður (Figure 1; Table 1).

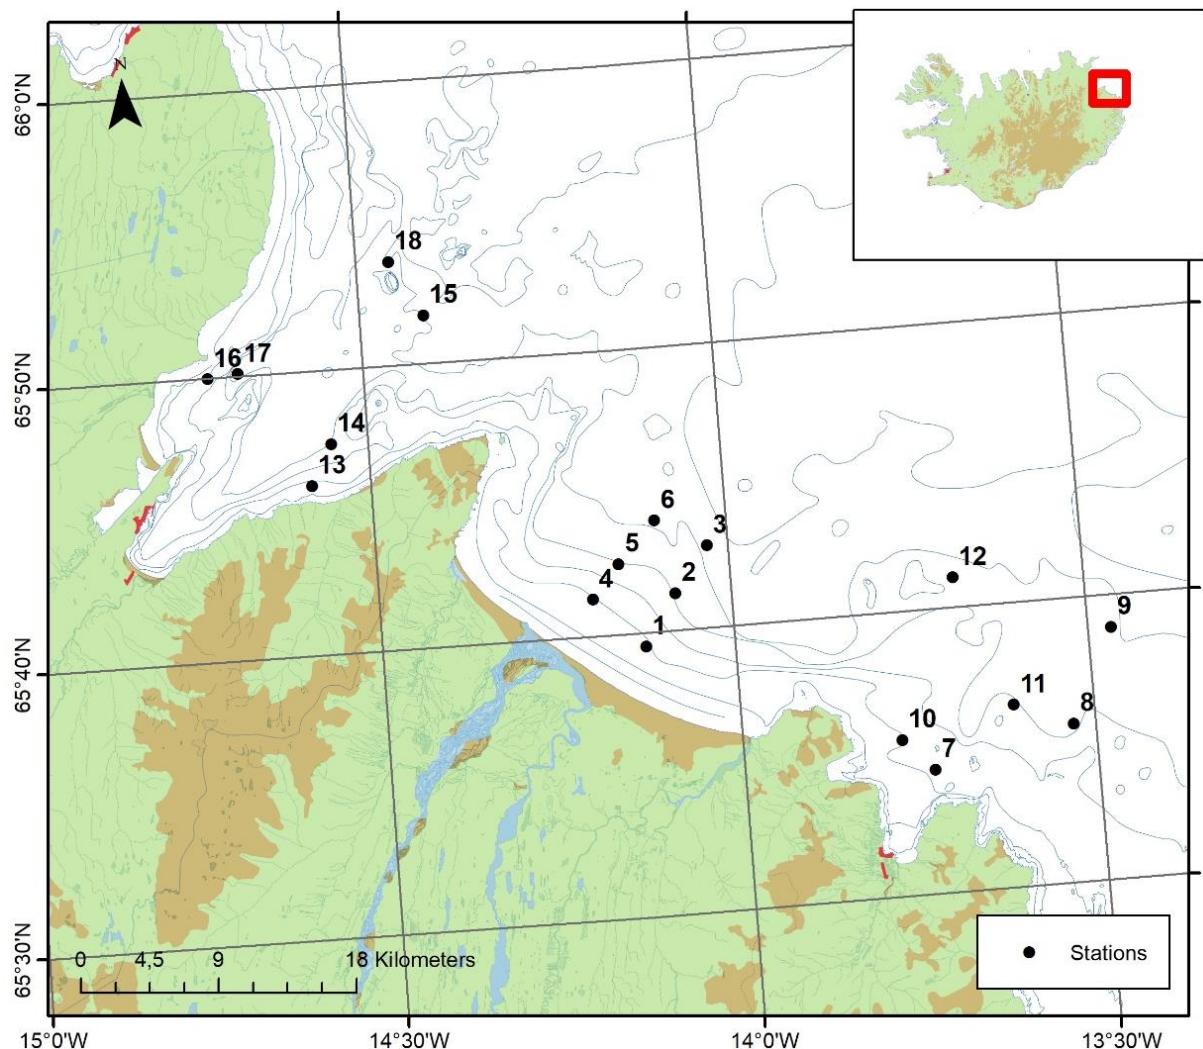

Figure 1 Location of 18 sampling stations in Héraðsflói (stations 1-6), Borgarfjörður eystri (stations 7-12) and Vopnafjörður (stations 13-18) in 2006 and 2019.

Mynd 1 Staðsetning 18 sýnatökustöðva í Héraðsflóá (stöðvar 1-6), Borgarfirði eystri (stöðvar 7-12) og Vopnafirði (stöðvar 13-18) í rannsóknum 2006 og 2019.

Samples for biological analyses was sieved through a 1 mm mesh size, round holes sieve, and stored in 4 % seawater-formaldehyde solution with borax to buffer the pH-level and rose-bengal for staining of animals for easier sorting. In the lab, the samples were washed free of formalin, sorted and identified to lowest possible taxonomic unit.

The upper 5 cm of undisturbed sediment layer were taken with a tube for analyses of Total Organic Content (TOC) and sediment grain size. At all stations, hydrographic measurements of salinity, temperature, density and oxygen saturation, were carried out for vertical profiles from surface to bottom. These measurements were made by a Sensordata CTDO 204 probe.

Table 1 Location of stations for biological and sediment sampling in East Iceland, June – July 2019.

2.2 Statistical analyses of data

Multivariate analyses of community composition between the sediment types were performed in det statistical software program PRIMER. v. 7.0.13. Abundance data were treated with fourth-root transformation. Bray-Curtis similarity coefficient (Bray and Curtis, 1957) were used to compute the similarities in the communities. Non-Metric Multidimensional Scaling (nMDS) (Kruskal and Wish, 1978) and Hierarchical Cluster Analysis were used to visualise the patterns in the communities. Analysis of Similarities (ANOSIM) was used to test if communities were statistically significant different (Clarke *et al.* 2014).

Three sediment types (sand, mixed and clay) were used as a factor to distinguish or observe patterns in the communities. Stations that contained > ~70 % sand (>0.063mm) were grouped as stations with sediment type *sand*. Stations that contained ~ 70 % silt and clay (<0.063mm) were grouped as stations with sediment type *clay* and stations with sediment type *mix* had comparable amounts of sand and clay.

3 Results

3.1 Héraðsflói (stations 1 – 6)

3.1.1 Hydrographical profiles

The hydrographical profiles for the two transects in Héraðsflói, which consisted of three stations each, can be seen in Figure 2. An overall trend was observed at all stations where the upper water masses had a weak stratification layer with higher temperature, lower salinity and higher oxygen concentration. Stratification layer was even stronger at st.1 and st.4 closest to the shore. Oxygen concentration was highest in the upper water masses and slightly declined below the stratification layer but were above 80 % in the bottom water.

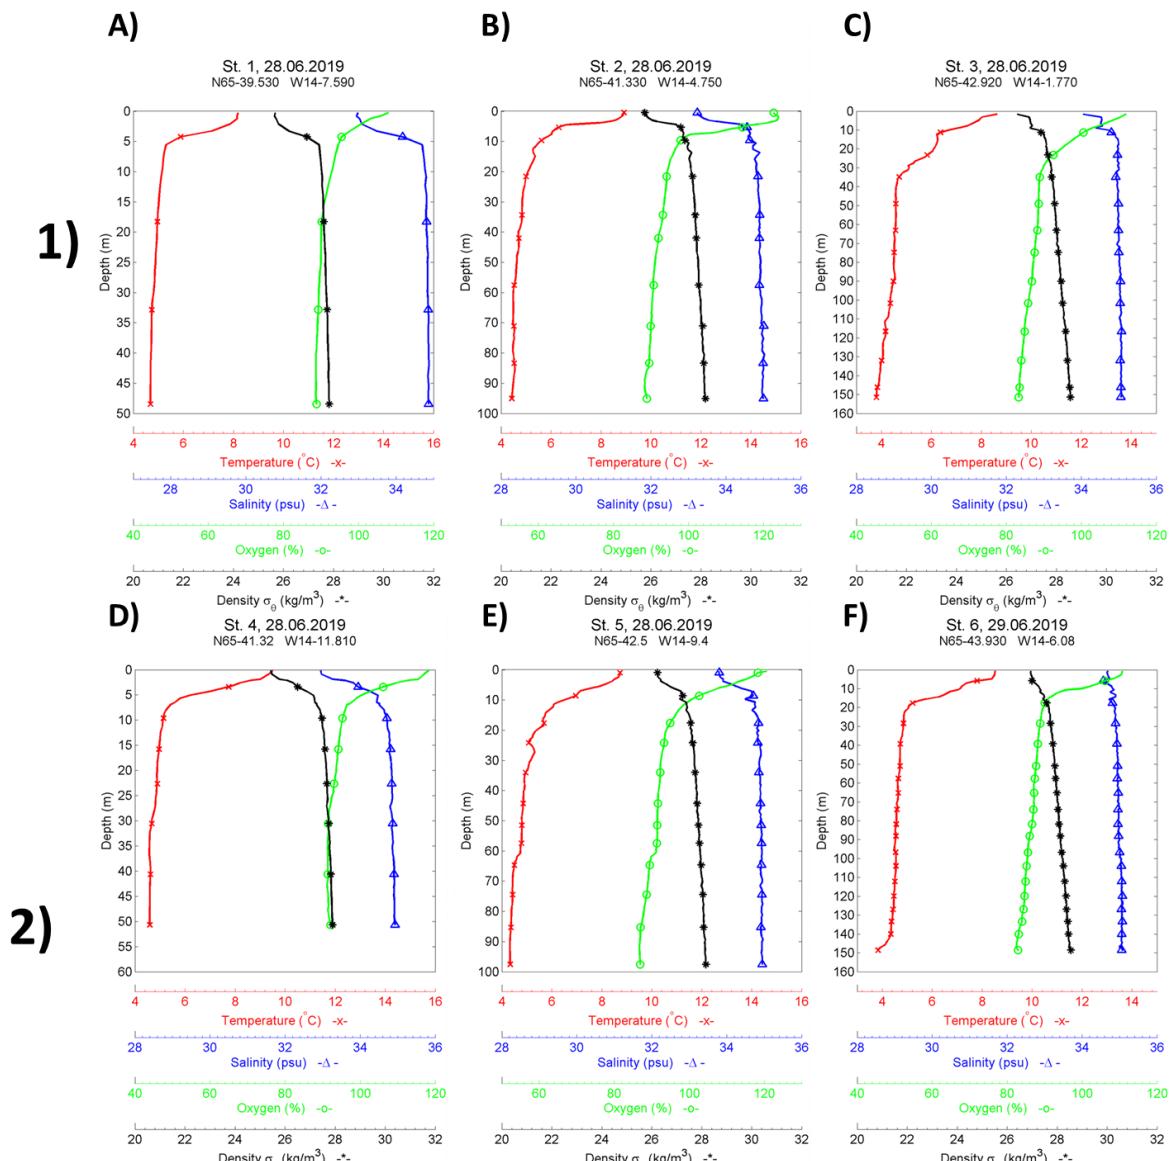

Figure 2 Hydrographical profiles for the two transects (1 and 2) in Héraðsflói, which consisted of three stations each. **A)** Station 1, **B)** Station 2, **C)** Station 3, **D)** Station 4, **E)** Station 5 and **F)** Station 6, June 2019.

Mynd 2 Prófílar með niðurstöðum sjómælinga fyrir sniðin tvö í Héraðsflóa sem hvort um sig samanstendur af þremur sýnatökustöðvum. A) Stöð 1, B) Stöð 2, C) Stöð 3, D) Stöð 4, E) Stöð 5 og F) stöð 6, í júní 2019.

3.1.2 Geochemical analyses and sediment description

The sediment composition and Total Organic Carbon (TOC) in Héraðsflói varied from the shallowest to the deepest station and can be seen in Table 2. Station 1 and station 4 were the shallowest stations and had highest percentage of sand (>0.063 mm) in the samples (95.6 and 80.4 %, respectively). The amount of clay (pelite) increased at the deeper stations. TOC in the sediment were lowest at the shallowest stations near shore and increased with depth. The Carbon-Nitrogen ratio (C/N) were higher at the shallowest stations and decreased with depth and was highest at station 1 (C/N: 13.8).

Table 2 Overview of the sediment content of Total Organic Carbon (TOC mg/g), Total nitrogen (TN mg/g), Carbon to Nitrogen ratio (C/N), sediment grain size in percentage pelite and sand (>0.063 mm) from the stations in Héraðsflóa, June – July 2019.

Tafla 2 Yfirlit yfir magn í botnseti af Heildar lífrænt kolefni (TOC mg/g), Heildar köfnunarefni (TN mg/g), hlutfall kolefna og köfnunarefnis (C/N), kornstærð botnsets sem hlutfall leirkennðs efnis og sands (>0.063 mm) fyrir sýnatökustöðvar í Héraðsflóa, júní – júlí 2019.

3.1.3 Species composition

Among the six stations at the two transects in Héraðsflói, the number of taxa that were present varied from 33 at station 1 to 83 taxa at station 2 (Table 3). Number of individuals varied from 2990 ind./m² at station 1 to 29145 ind./m² at station 2. Station 2 had the highest number of taxa and abundance. The shallowest stations (station 1 and station 4) had the lowest number of taxa and abundance. The Shannon-Wiener diversity index (H') were highest at the shallowest stations near shore and had a varying decrease with increasing depth. Lowest SW index (H'=1.36) was seen at station 2 which had the highest number of taxa and abundance. Pielou evenness index (J') varied across the stations and were high at the shallowest station near shore and had a slightly and varying decrease with depth (Table 3).

Table 3 Number of species and individuals per m². H' = Shannon-Wieners diversity index. ES₁₀₀= Hurlberts diversity index. NQI1 = overall index (diversity and sensitivity). ISI2012= sensitivity index. NSI = sensitivity index. J = Pielous evenness index. AMBI = AZTI marine biotic index (part of NQI1). nEQR = normalized EQR.

Tafla 3 Fjöldi tegunda og einstaklinga per m². H' = Shannon-Wieners stuðull. ES₁₀₀= Hurlberts fjölbreytileika stuðull. NQI1 = heildar stuðull (fjölbreytileiki og næmni). ISI2012= næmnistuðull. NSI = næmnistuðull. J = Pielous einsleitnistiðull. AMBI = AZTI marine biotic index (hluti af NQI1). nEQR = normalized EQR.

6	68	14 075	2.00	12.19	0.68	9.62	20.18	0.59	2.46	0.38

The main features of the species composition across the six stations in Héraðsflói are shown in the form of a top ten species list from each station in Table 4. The species are also divided into five ecological groups (EG) based on the value of the sensitivity index. These groups run from sensitive species (group I) to pollution indicator species (group V). The tolerant polychaeta *Galathowenia oculata* (group III) were the most dominant species across all stations followed by the sensitive polychaeta *Maldane sarsi* (group I) or the tolerant bivalve *Arctica islandica* (ecological group III). *Galathowenia oculata* contributed between 51 – 80 % of the total number of individuals at the stations.

Table 4 Number of individuals per m², cumulative percentage and AMBI ecological groups* for the ten most dominant species on the stations from East Iceland in 2019.

3.2 Borgarfjörður eystri (stations 7 – 12)

3.2.1 Hydrographical profiles

The hydrographical profiles for the two transects in Borgarfjörður eystri, which consisted of three stations each, can be seen in Figure 3. An overall trend was observed at all stations where the upper water masses had a weak stratification layer with higher temperature, lower salinity and higher oxygen concentration, except station 12, which had homogenous water masses. Oxygen concentration was highest in the upper water masses and slightly declined below the stratification layer but were above 80 % in the bottom water.

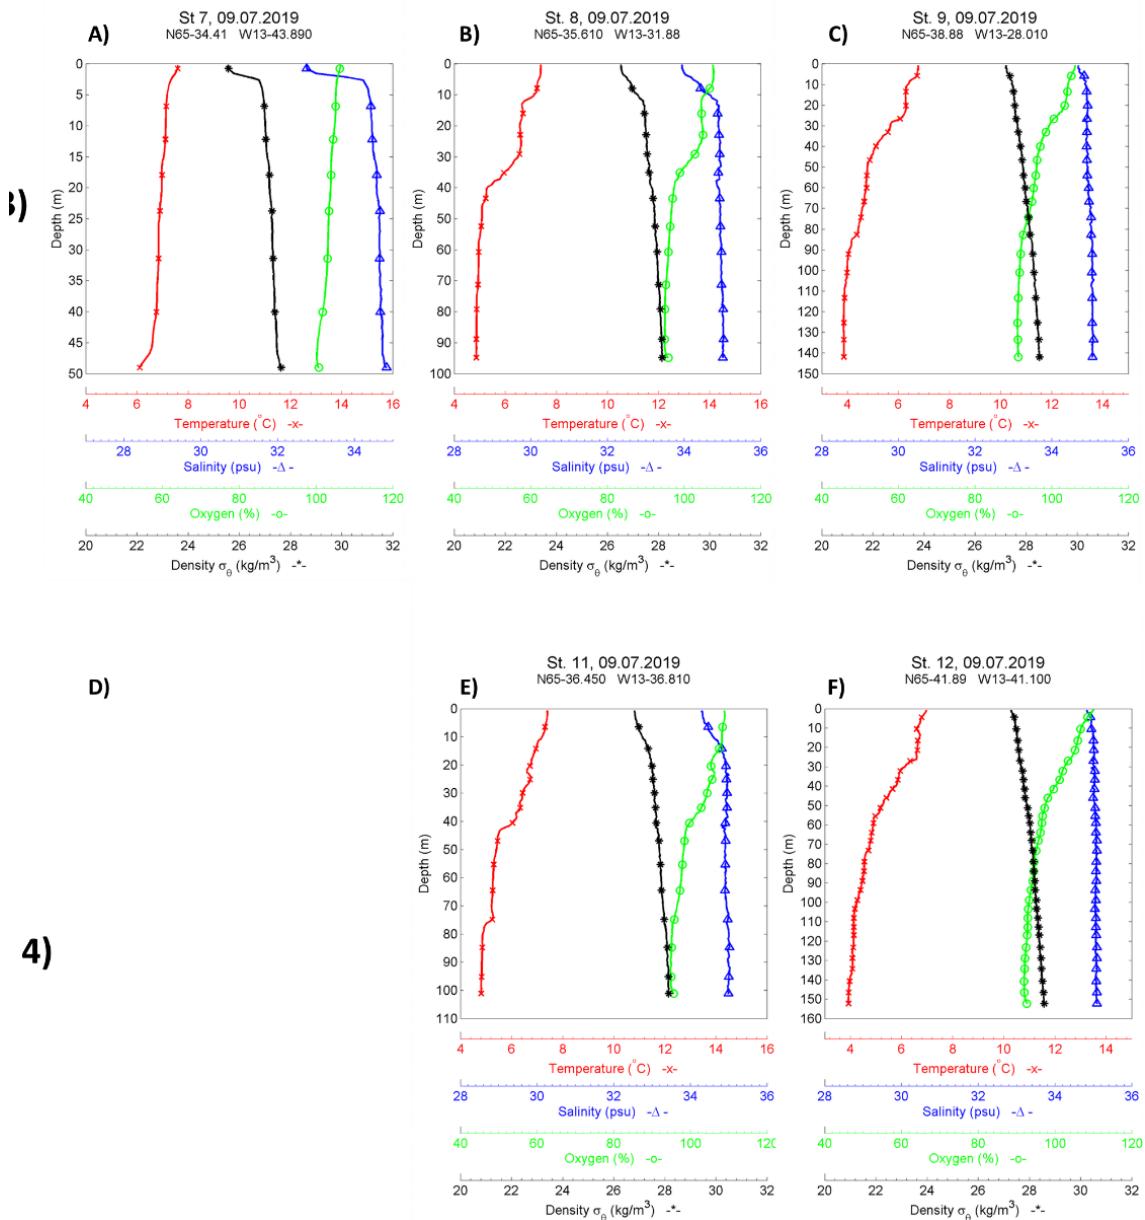

Figure 3 Hydrographical profiles for the two transects (1 and 2) in Borgarfjörður eystri, which consisted of three stations each. **A)** Station 7, **B)** Station 8, **C)** Station 9, **D)** Station 10 (error in dataset), **E)** Station 11 and **F)** Station 12 that were taken in June 2019.

3.2.2 Geochemical analyses and sediment description

The sediment composition and Total Organic Carbon (TOC) in Borgarfjörður varied from the shallowest station to the deepest and can be seen in Table 5. Station 7 and 10 were the shallowest stations and had highest percentage of sand (>0.063 mm) in the samples (81.8 and 85.9 %, respectively). Percentage of clay (pelite) increased at the deeper stations. TOC in the sediment were lowest at the shallowest stations near shore and increased with depth. The Carbon-Nitrogen ratio (C/N) were higher at the shallowest stations and decreased with depth.

Table 5 Overview of the sediment content of Total Organic Carbon (TOC in mg/g), Total nitrogen (TN in mg/g), Carbon to Nitrogen ratio (C/N), sediment grain size in percentage pelite and sand (>0.063 m) from the stations in Borgarfjörður taken in June – July 2019 by Akvaplan-niva.

3.2.3 Species composition

Among the six stations distributed over the two transects in Borgarfjörður eystri (Figure 3), the number of taxa varied from 41 at station 7 to 145 taxa at station 11 (Table 6). Number of individuals varied from 5 310 ind./m² at station 7 to 10 675 ind./m² at station 11. Station 11 had both the highest number of taxa and abundance. The two shallowest stations (station 7 and 10) had the lowest number of taxa and abundance. The Shannon-Weiner diversity index (H') was highest at station 8 (4.82) and lowest at station 7 (2.15). Pielou eveneness index (J') varied across the stations in Borgarfjörður and was high at station 8 (0.76) and low at station 7 (0.45). There was no clear pattern in either H' or J' with increasing depth.

Table 6 Number of species and individuals per m². H' = Shannon-Wieners diversity index. ES₁₀₀= Hurlberts diversity index. NQI1 = overall index (diversity and sensitivity). ISI2012= sensitivity index. NSI = sensitivity index. J = Pielous evenness index. AMBI = AZTI marine biotic index (part of NQI1). nEQR = normalized EQR.

Tafla 6 Fjöldi tegunda og einstaklinga per m². H' = Shannon-Wieners stuðull. ES100= Hurlberts fjölbreytileika stuðull. NQI1 = heildar stuðull (fjölbreytileiki og næmni). ISI2012= næmnistuðull. 12	112	9840	3.29	24.67	0.77	10.89	21.83	0.72	1.92	0.55

The main features of the species composition across the six stations in Héraðsflói are shown in the form of a top ten species list from each station in Table 7. The species are also divided into five ecological groups (EG) based on the value of the sensitivity index. These groups run from sensitive species (group I) to pollution indicator species (group V). The tolerant polychaeta *Galathowenia oculata* (group III) were the most dominant species across all stations and mainly followed by the sensitive polychaeta *Maldane sarsi* (group I). *Galathowenia oculata* contributed between 19 – 69 % of the total number of individuals at the stations.

3.3 Vopnafjörður (stations 13 – 18)

3.3.1 Hydrographical profiles

The hydrographical profiles for the two transects in Vopnafjörður are presented in Figure 4. Station 13 showed the strongest stratification layer compared to the other stations. An overall trend was observed at all stations where temperature was higher and salinity lower in the upper water masses. Oxygen concentrations were highest in the upper water masses and slightly declined below the stratification layer but were above 80 % in the bottom water.

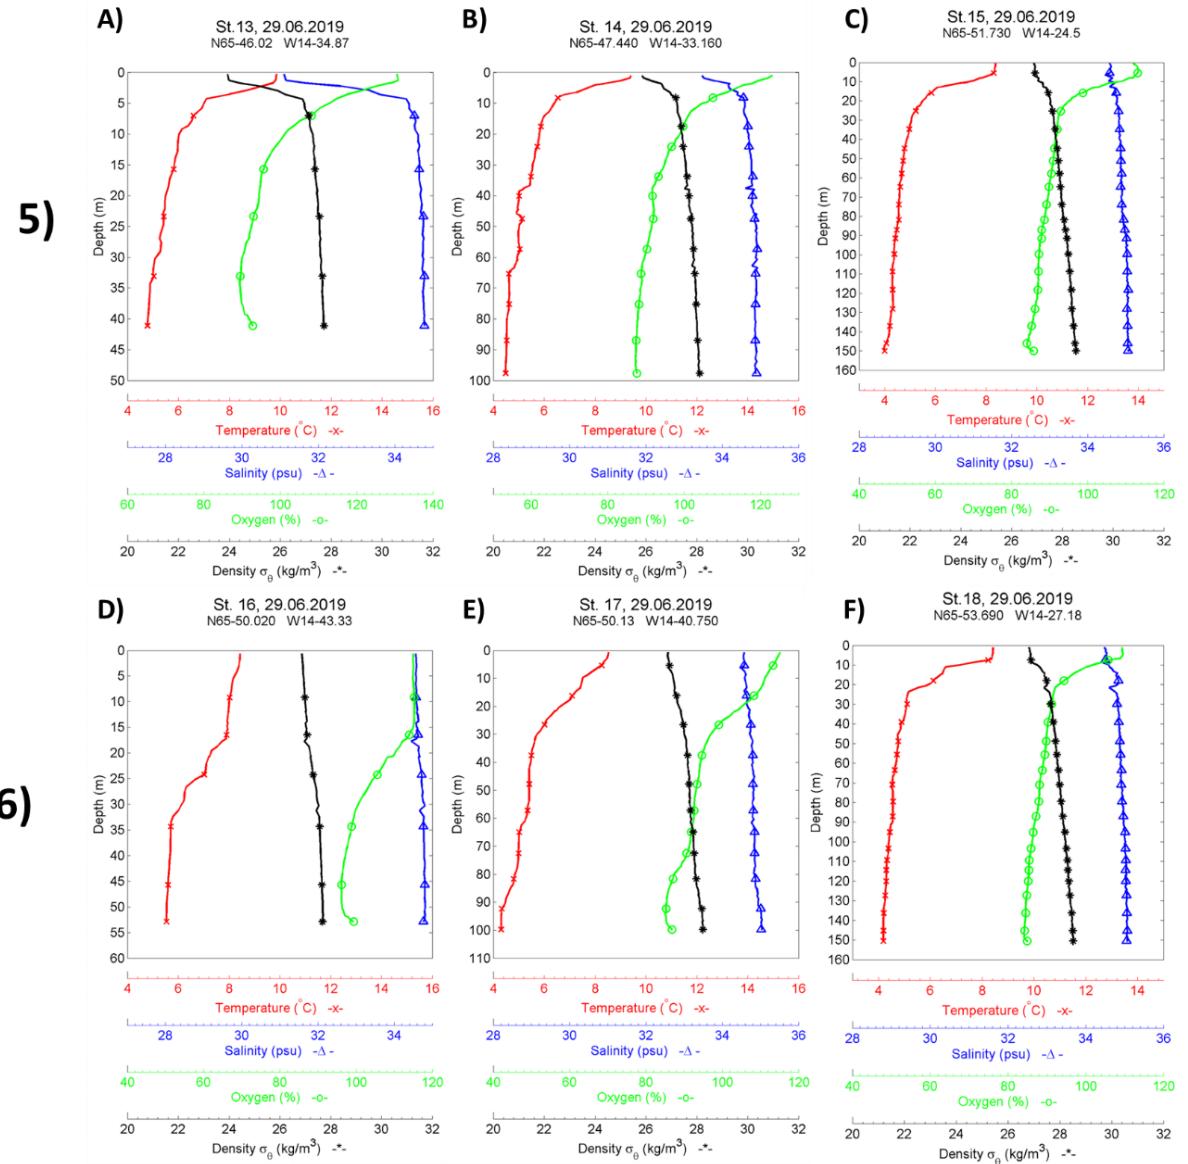

Figure 4 Hydrographical profiles for the two transects (5 and 6) in Vopnafjörður, which consisted of three stations each. **A)** Station 13, **B)** Station 14, **C)** Station 15, **D)** Station 16, **E)** Station 17 and **F)** Station 18, June 2019.

3.3.2 Geochemical analyses and sediment description

The sediment composition and Total Organic Carbon (TOC) in Vopnafjörður varied from the shallowest station to the deepest and can be seen in Table 8. Stations 13 and 18 were the

shallowest stations and had highest percentage of sand (>0.063 mm) in the samples (80.7 and 70.2 %, respectively). Percentage of clay (pelite) increased from the shallowest station to approximately 100 m, and decreased to equal amount of sand and clay at the deepest stations 15 and 18. TOC in the sediment were lowest at the shallowest stations near shore and increased to the deeper stations at ca. 100 m, and subsequently decreased a little to the deepest station at 150 m depth. The Carbon-Nitrogen ratio (C/N) varied across the depths but did not show explainable pattern with depth.

Table 8 Overview of the sediment content of Total Organic Carbon (TOC in mg/g), Total nitrogen (TN in mg/g), Carbon to Nitrogen ratio (C/N), sediment grain size in percentage pelite and sand (>0.063 m) from the stations in Vopnafjörður taken in June – July 2019 by Akvaplan-niva.

Tafla 8 Yfirlit yfir magn í botnseti af Heildar lífrænt kolefni (TOC mg/g), Heildar köfnunarefni (TN mg/g), hlutfall kolefna og köfnunarefnis (C/N), kornstærð botnssets sem hlutfall leirkennðs efnis og sands (>0.063 mm) fyrir sýnatökustöðvar í Héraðsflóa, júni – júlí 2019.

3.3.3 Species composition

Among the six stations distributed over the two transects in Vopnafjörður (Figure 1), the number of taxa varied from 57 at station 17 to 124 taxa at station 16. Number of individuals varied from 3040 ind./m² at station 13 to 17 645 ind./m² at station 18 (Table 9). The two shallowest stations had the highest number of taxa. The Shannon-Weiner diversity index (H') were highest at station 13 (5.42) and lowest at station 15 (1.74). Pielou evenness index (J') varied across the stations in Vopnafjörður and was high at station 13 (0.90) and low at station 15 and 18 (0.33). H' decreased with increasing depth and J' had no clear pattern with changing depths.

Table 9 Number of species and individuals per m². H' = Shannon-Wieners diversity index. ES₁₀₀= Hurlberts diversity index. NQI1 = overall index (diversity and sensitivity). ISI2012= sensitivity index. NSI = sensitivity index. J = Pielous evenness index. AMBI = AZTI marine biotic index (part of NQI1). nEQR = normalized EQR.

Tafla 9 Fjöldi tegunda og einstaklinga per m². H' = Shannon-Wieners stuðull. ES₁₀₀= Hurlberts fjölbreytileika stuðull. NQI1 = heildar stuðull (fjölbreytileiki og næmnvi). ISI2012= næmniststuðull. 3.4 Seafloor communities

3.4.1 Taxa composition at all sites

During the sampling in June – July 2019, a total of 317 taxa were collected from all stations. The taxa distribution across the phyla can be seen in Figure 5. The taxonomical group Polychaeta were the superior dominant in the species list with 91 % of the total taxa. Mollusca was the following taxonomical group that contributed to 71 taxa of the total taxonomical list with 5 % and Crustacea with 56 taxa (3 %). The station with most taxa was station 11 with 145 taxa and the station with the least taxa was station 1 with 33 taxa.

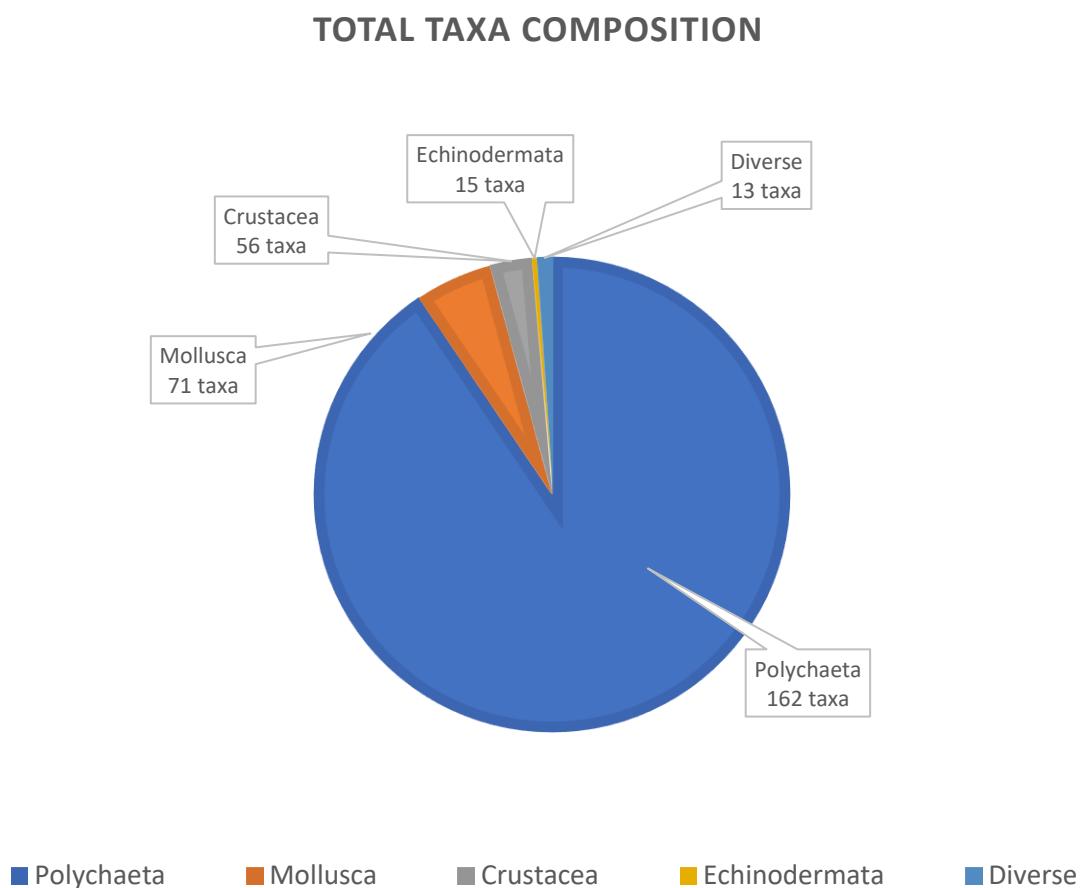

Figure 5 The proportion of invertebrate taxonomic composition by phyla that was collected in East Iceland in June – July 2019 by Van veen Grab.

Mynd 5 Hlutfall hryggleysingja eftir fylkingum í sýnum sem safnað var á Austurlandi í júni – júlí 2019 með Van veen greip.

3.4.2 Seafloor communities in comparison

Hierarchical cluster analysis and nMDS plot are shown as Figure 6 A B to visualise if any stations had any distinctive taxa. It was possible to see that most of the stations containing factor sandy sediment were somewhat ordinated closely together, whereas the stations with factors clay and mixed sediment did not show a distinct separation.

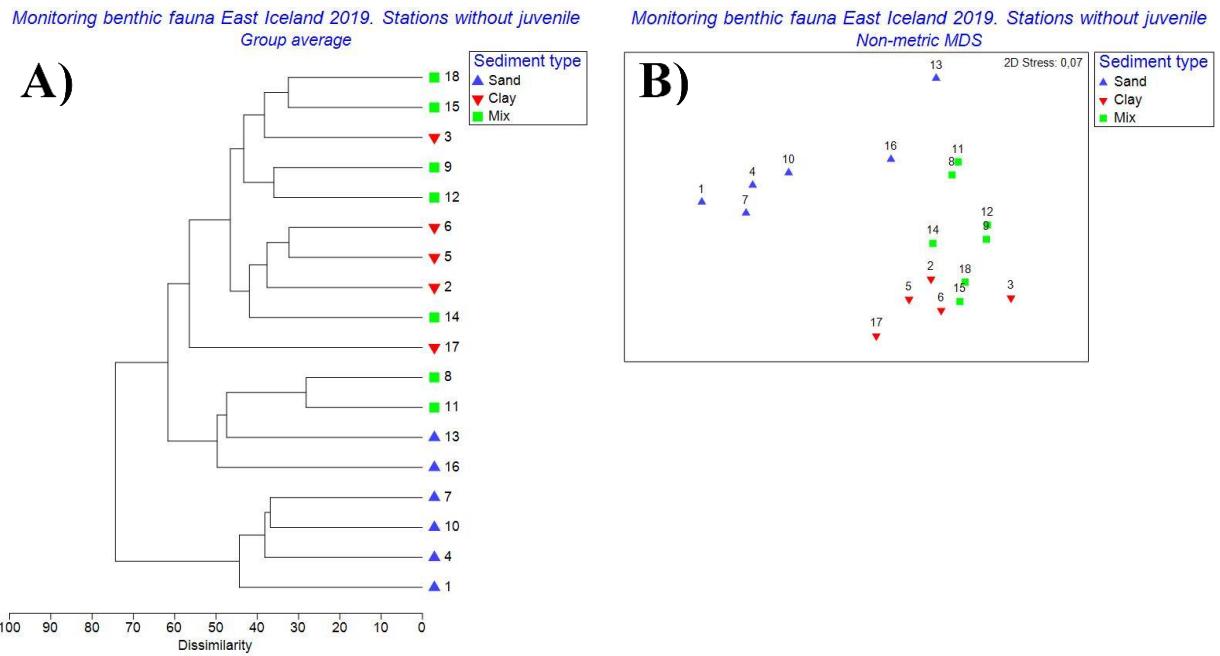

Figure 6 Grouping of the stations based on factor sediment type in East Iceland 2019 by **A**) Hierarchical Cluster Analysis, group average and **B**) non-Metric Multidimensional Scaling (nMDS).

Mynd 6 Flokkun sýnatökustöðva eftir tegund botngerðar á Austurlandi 2019 skv. A) Klasagreiningu, meðaltal hópa og B) nMDS greiningu.

Analysis of Similarities (ANOSIM) was conducted on the factor sediment type to see if there were any statistically significant differences in taxa composition at the different stations due to sediment composition (Table 11). ANOSIM suggested that there was a statistically significant difference ($p = 0.001$, $R = 0.58$) in taxonomical composition between the different sediment types Sand, clay and mix. R statistic suggested a strong separation between the factors sand and mix as well as sand and clay.

Table 11 Results from one-way ANOSIM test. Test was conducted to see if there were any statistically significant difference in the seafloor communities due to the sediment types sand, mix and clay. Showing groups, R statistic, significance level, possible permutations, actual permutations and number observed. “

4 Discussion

4.1 Comparison between Héraðsflóa and reference sites

The sediment grain size across the stations seem not to show a big difference from Héraðsflói to the reference sites. All transects and stations within the sites had similar trend, where the shallowest stations had higher proportion of sand in sediment and there was a general higher clay content with increasing depth. The same trends could also be seen in TOC-levels. C/N-ratio at station 1 were recorded as the highest and above values that are common for marine sediments, which can also indicate that this station is more influenced by terrestrial input than the others.

In addition to the sandy stations in Héraðsflói, there were also found sandy stations at the reference sites and were ordinated in the Hierarchical Cluster Analysis and nMDS (Figure 6 A and B) as more similar in taxonomic composition than the stations belonging to the same bay system, indicating no differences in the seafloor communities between Héraðsflói and the reference sites. This was also proven when ANOSIM test was conducted (Table 12). The list of the top ten most frequent taxa showed that there were some recurring species across the stations (e.g. *Galathowenia oculata* were found at all stations).

4.2 Comparison to previous survey in 2006

The survey conducted in 2006 did not show large variation in faunal communities between Héraðsflói and the other two reference locations but showed rather similar communities based on sediment type (sand, mixed and clay; Ólafsdóttir *et al.* 2007). Two separate groupings were observed, where faunal communities in sandy sediment at the stations were considered as one group and communities with mixed and clay sediment as the other group. The results from the survey conducted in 2019 showed the same general trend, where the faunal communities were grouped by sediment type. Sandy sediment type was mostly found in the shallow areas at ca. 50 m, whereas mixed and clay sediment were found at deeper depths of 100 – 150 m in both surveys.

The sediment composition in Héraðsflói showed small changes since the first survey was carried out and there has been a slight increase in the proportion of sand at station 1, which can explain the changes in the number of taxa from 63 in 2006 to 33 in 2019. It is also interesting to note that the lowest abundance recorded in the 2019 survey was at station 1, which was not the case for station 1 in 2006 (Table 13). A decrease in Shannon Wiener diversity index was also recorded at station 1 from 2006 to 2019. Even if the number of taxa decreased at station 1 in Héraðsflóa between the two surveys, it is possible to see that the number of taxa is either comparable or trending higher at the other stations between the surveys (Table 13). In addition to a decrease in number of taxa, there was also observed a shift in taxonomical composition at station 1 (closest to the river discharge area) between the two surveys after the start-up of the Kárahnjúkar dam. The polychaeta *Sabellides borealis* was the dominant species in terms of abundance at station 1 in 2006 but was not observed at the same station in the 2019 survey. Instead, the polychaeta *Galathowenia oculata* was observed to dominate the fauna at station 1 in 2019. The changes in taxonomical composition can be linked to the high C/N-ratio at station 1, which is an indication of terrestrial input to the marine system. It was suspected that after starting of the powerplant there would be higher ratio of less coarse material entering the Héraðsflói. The slightly higher proportion of sand at station 1 could seem contradictory to this but it could indicate that that there has also been a reduction in clay and finer sediments entering the Héraðsflói. Further studies might give more information about these changes if they are

merely the results of annual fluctuations or can be linked to long term changes in the amount of sand and clay in the river effluent.

Consequently, one would have assumed that finding only 174 taxa in 2006 compared to 317 taxa in 2019 is somewhat contradictory when it is known that the first survey used a mesh size of 500µm (possibility to catch smaller organisms), whereas the recent survey used a larger mesh size of 1 mm. However, these two surveys have been conducted with span of thirteen years, with no recordings in annual fluctuations, which is important to keep in mind that natural fluctuations within a year can occur and has not been observed for this case study.

The survey conducted in 2006 mentioned some challenges in counting the polychaeta *Galathowenia oculata* due to its slimy polychaeta tube and suggested that the counting could have been unprecise. Even though the uncertainty is mentioned, the number of *Galathowenia oculata* did not show a clear trend with depth and sites and between the years, and can be due to inconsistent use of mesh size between the surveys, where they in 2006 could have managed to sample smaller *G. oculata* than the recent year.

Table 13 Summary of the percentage clay and sand for 2006 and 2019, Total Organic Matter (TOM) in % for 2006 and Total Organic Carbon in mg/g for 2019, number of taxa, number of individuals per m² and Shannon Wiener diversity index (H') at the stations in Héraðsflói, Borgarfjörður, and Vopnafjörður in East Iceland. Numbers in grey cells are from the survey in 2006 and white cells are numbers from survey in 2019. Bold numbers in the cells are showing the minimum value and the maximum value.

5 Conclusion

The survey carried out in 2006 did not show large variation in faunal communities between Héraðsflói and the other two reference locations but showed rather similar communities based on sediment type. Two separate groupings were observed, where faunal communities that contained sandy sediment at the stations were considered as one group and communities with mixed and clay sediment were the other group. The results from the present survey in 2019 showed the same trend, where the faunal communities were grouped by sediment type, and not a distinct separation of Héraðsflóa and the reference sites. However, it was observed that station 1 closest to the river input in Héraðsflóa experienced some changes in sediment composition, reduction in abundance and number of taxa and changes in taxa composition between the two surveys which could be related to river discharges, but also annual changes. The overall taxonomical composition at the different study sites in 2019 looks similar to the case study in 2006, and no major changes related to the possible changes in the river outflow were apparent.

- Result in the 2019 survey are in general comparable with results from the 2006 survey in terms no distinctive difference in the faunal communities between Héraðsflói and the reference sites.
- Distinctive faunal communities related to sediment type (sand and mix of sand/clay).
- Some changes in sediment composition at station 1 (Héraðsflói) and reduction in taxa composition between years could be related to changes in river discharges or merely reflect annual changes.
- Overall, no major changes in the taxonomical composition observed related to the possible changes in the rive outflow.

Appendices

6.1 Appendix 1. Statistic methods applied to the soft bottom fauna

Diversity indices

Diversity indices describe the diversity of an animal or plant community in an area or at a specific site. Several diversity indices exist and are widely applied in monitoring studies. Some indices focus mainly on number of species (species richness), while other address the distribution of individuals between species (measures of evenness or dominance). Different indices thus highlight different aspects of the faunal community

Diversity indices are "classical" in surveys of contamination and discharges as environmental disturbance often is expressed in changes of the species and individuals distribution of the community. A weakness, however, related to diversity indices is that changes are not always discovered, as one species may replace another in the same number of individuals, and thus not trigger any changes of the calculated indices.

Shannon-Wieners index (Shannon & Weaver, 1949) is calculated by the formula:

$$H' = -\sum_{i=1}^s \frac{n_i}{N} \log_2 \left(\frac{n_i}{N} \right)$$

Where n_i = number of individuals of species i found in the sample

N = total number of individuals

s = number of species

This index includes both number of species and the distribution among species, and this index is more sensitive for changes in the distribution of individuals. A low index value characterises a species poor community and dominance of a limited number of species. A high index value describes a community rich in species (and presumably without major human disturbance)

Pielous evenness index (Pielou, 1966)

Is calculated according to the below formula

$$J = \frac{H'}{\log_2 s}$$

Where n_i = number of individuals of species i found in the sample

N = total number of individuals

s = number of species

Hurlbert's diversity curves

A graphic expression of diversity often applied is the plot of number of species versus number of individuals. Based on total number of species and individuals in a sample, an expected number of species to be found in a subsample consisting of fewer individuals is calculated. The measure of diversity thus becomes independent of the size of the sample and opens for comparison among sites with varying numbers of individuals. Hurlbert (1971) has developed a procedure to calculate such diversity curves based on probability calculations:

ES_n is expected number of species in a subsample consisting of n randomly chosen individuals from a sample containing a total of N individuals belonging to s number of species, and is expressed as:

$$ES_n = \sum_{i=1}^s \left[1 - \frac{\binom{N-N_i}{n}}{\binom{N}{n}} \right]$$

der N = total number of individuals in the sample

N_i = number of individuals of species i

n = number of individuals in a given subsample (of N)

s = total number of species in the sample

Plot of number of species versus number of individuals

The species are divided in groups/classes according to number of individuals occurring in a sample. Usually class I = 1 individual pr. species, class II = 2-3 individuals, class III = 4-7 individuals, class IV = 8-15 individuals, etc.

The lower class limit will make up a chain of segments defined by the formula 2^x , $x=0,1,2, \dots$. This is referred as a chain of geometrical classes. If the number of species in each class is plotted against the class on a linear scale, a curve illustrating the distribution of individuals among species in the community will appear. Experience shows that samples from undisturbed soft bottom faunal communities contains many species with few individuals, and few species with high numbers of individuals. This gives rise to a unimodal, asymmetric curve with a long tail of high class numbers (with few individuals). In most cases this type of curve is fitted well to a log-normal distribution.

In cases of moderate organic load, or contamination, some of the individual-poor species will disappear, while species being able to cope with the changed conditions will increase in numbers. This will make the curve flatten (lower starting point at the y-axis), it will tend to extent towards the higher geometric classes (as more species increase in numbers), or the curve may become bi- or trimodal. Under such circumstances, the curve loses any resemblance with the statistic log-normal distribution. Any deviations from the log-normal distribution may then be interpreted as an indication of disturbance. The changes of the curve is triggered at an early stage of environmental disturbance. By increasing disturbance only a few, but generally very numerous species will survive. The Log-normal resemblance may in this instance reappear, but with a lower stating point (top) and distributed over more classes compared to the originally undisturbed community.

Distribution patterns of the fauna

Variations in the distribution patterns of the fauna across a sampling area are assessed by comparing the density (number) of species per station. For this purpose, multivariate classification and ordination analyses (Cluster and/or MDS) are applied. The analyses in the current project were performed using the software package PRIMER v5. Input data are numbers of individuals per species per sample. The samples can be replicates (single grabs) or aggregated at station level (0.4 square meter). Only figures count, and it does not matter what species an individual belongs to. Prior to the MDS and cluster analyses, the species lists were double square root transformed to reduce the interval (spread) between high and low densities and reduce the influence of numerous species in the material.

Cluster analysis

This analysis examines the faunal resemblance among samples. To compare two samples, the Bray-Curtis index was calculated (Bray & Curtis, 1957):

$$d_{ij} = \frac{\sum_{k=1}^n |X_{ki} - X_{kj}|}{\sum_{k=1}^n (X_{ki} + X_{kj})}$$

Where n = number of species compared

X_{ki} = number of individuals of species k in sample no. i

X_{kj} = number of individuals of species k in sample no. j

The value of this index will decrease with increasing resemblance. The index value equals 1 if the samples are completely different (no common species). Identical species and numbers of individuals will yield an index value of 0. Samples are grouped pairwise, dependent on their degree of difference by "group-average linkage". Similar samples are presented in groups (clusters), and the final result is summarised in a three (dendrogram).

Sensitivity (AMBI, ISI and NSI)

Sensitivity is expressed by the indices ISI and AMBI. Calculation of ISI is described by Rygg (2002). The sensitivity index AMBI (Azti Marin Biotic Index) ascribes a sensitivity class (ecological group, EG) to each species: EG-I: sensitive species, EG-II: indifferent species, EG-III: tolerant species, EG-IV: opportunistic species, EG-V: indicators of contamination. The composition of the macro-invertebrate fauna and the share of the individual EG is an indicator for the extent of the disturbance/contamination.

NSI is a sensitivity index comparable to AMBI, but is developed based on Norwegian fauna data combined with a objective statistic method. The NSI of a sample is calculated as the average of the sensitivity scores of all individuals found in the sample.

Combined indices (NQI1 and NQI2)

NQI1 and NQI2 are calculated based on species diversity and sensitivity. NQI1 is applied in NEAGIG (The North East Atlantic Intercalibration Group). Most countries now apply combined indices like NQI1 og NQI2.

The NQI1 index is calculated as:

$$\text{NQI1 (Norwegian quality status, version 1)} = [0.5 * (1 - \text{AMBI}/7) + 0.5 * (\text{SN}/2.7) * (\text{N}/(\text{N}+5))]$$

The diversity index $\text{SN} = \ln S / \ln(\ln N)$, where S is number of species and N is number of individuals in the sample.

ANALYSERAPPORT Sedimentprøver

Kunde: Landsvirkjun
Kunde referanse: Øst Island sedimentovervåking
Kontaktperson kunde:
e-post:

Kontaktperson Akvaplan-niva: Lars-Henrik Larsen

Dato: 25.02.2020

Rapport nr.: 60935
Analyseparameter(e): Korn, TOC, TN
Kontaktperson: Janne B. Johnsen

Analyseansvarlig: *Oda Sofie Bye Wilhelmsen* (sign.)

Underskriftsberettiget: *Dian Toodee* (sign.)

Prøvene ble sendt/levert til Akvaplan-Niva AS av oppdragsgiver, og merket som angitt i tabellen på side 2.
Resultater av analysene er gitt fra side 3.

MERKNADER:

Prøve 8, 11, 14 og 16 inneholder skjellbiter større enn 15 mm som ikke er inkludert i kornanalysen. Skjellbitene ville utgjøre henholdsvis 3.3, 2.5, 1.2 og 1.8 vekt% av den totale prøven.

Analysene gjelder bare for de prøver som er testet. De oppgitte analyseresultat omfatter ikke feil som måtte følge av prøvetagningen, inhomogenitet eller andre forhold som kan ha påvirket prøven for den ble mottatt av laboratoriet. Rapporten får kun kopieres i sin helhet og uten noen form for endringer. En eventuell klage skal leveres laboratoriet senest en måned etter mottak av analyseresultat. Nærmere informasjon om analysemetodene (måleusikkerhet, metodeprinsipp etc.) fås ved henvendelse til Akvaplan-Niva AS
